## How Should The Sardine Length Frequencies Be Weighted?

## C.L. de Moor* and D.S. Butterworth*

Length frequencies are calculated for the annual sardine November surveys using samples from trawls undertaken during the spawner biomass acoustic surveys and using a method of calculation that was developed by Roel and probably also Hampton (Coetzee pers. comm.). These length frequencies are used in estimating the acoustic biomass and the proportion-at-age at the time of the survey.

This document briefly considers the current method used to estimate the survey length frequency and develops some alternative methods. The implications of the alternative methods will be discussed in a future document.

## Method

The method currently used to calculate the length frequency of the spawner biomass survey is detailed in Appendix A. In essence, the length frequencies from the individual trawls are weighted by the acoustic weighting associated by that trawl as a proportion of the total of the acoustic weighting of all trawls. A new method, termed "alternative method" for the sake of this document, has been developed with the following in mind (see Appendix B):
i) the logic behind calculating the weightings (equations A. 2 to A.4) in the current method is unclear;
ii) the individual trawls and their proportions-at-length are weighted using the acoustic density in the manner assumed to underlie the current method; and
iii) a method with logical steps was required, in which the weighting factor applied to each trawl was clear and easily modified given changed assumptions.

Using the alternative method, a comparison is made of the November survey proportions-at-age (see Appendix C) calculated using:
I) the length frequency for the full survey area together with the age-length-key calculated using samples from the full survey area;
II) the length frequency together with the age-length-key using data up to Port Alfred only; and
III) the length frequency using data up to Port Alfred only together with the age-length-key calculated using samples for the full survey area.

Option III) is what is currently being used, while option II) would appear to be the best choice for use in assessments to correspond with the use of survey biomass up to Port Alfred only.

[^0]The standard deviation and CVs of the estimated proportions-at-age and proportions-at-length are calculated from 1000 bootstrapped iterations of option II) above (see Appendix D). This is done only for years in which survey age-length keys were available (1993, 1994, 1996, 2001, 2002, 2003, 2004, 2006), since the age-lengthkey using commercial data up to Port Alfred only was not easily obtainable.

## Results

## Comparing the Alternative Method to the Current Method

The current and alternative methods both result in the same total proportion-at-length for the survey (results not shown). However, the numbers-at-length (or the "length frequency") differ by a constant per stratum between the two methods. Comparing equations (A.4) and (B.8), it is not possible to find an analytical solution to this constant per stratum. Substituting in, one can see that from equation (A.4) we have:
$N_{s l}=\frac{T_{s l} \cdot B_{s}}{\sum_{j} Z_{s j}}=\left(\frac{B_{s}}{\sum_{j} Z_{s j}}\right) \sum_{j}\left(T_{s j l} \cdot \frac{Z_{s j}}{W_{s j}}\right)$
while equation (B.8) gives:

$$
\begin{aligned}
N_{s l} & =p_{s l} \cdot N_{s}=\left(\sum_{j} p_{s j l}^{t r a w l} \cdot \frac{N_{s j}}{N_{s}}\right) \cdot N_{s}=\sum_{j} p_{s j l}^{t r a w l} N_{s j}= \\
& =\sum_{j}\left(\frac{T_{s j l}}{\sum_{l} T_{s j l}} \cdot k_{s} \frac{Z_{s j}}{\bar{W}_{s j}}\right)=\sum_{j}\left(\frac{T_{s j l}}{\sum_{l} T_{s j l}} \cdot \frac{B_{s}}{\sum_{j} Z_{s j}} \cdot Z_{s j} \cdot \frac{T_{s j}}{W_{s j}}\right)=\left(\frac{B_{s}}{\sum_{j} Z_{s j}}\right) \sum_{j}\left(T_{s j l} \cdot \frac{Z_{s j}}{W_{s j}} \cdot \frac{T_{s j}}{\sum_{l} T_{s j l}}\right)
\end{aligned}
$$

Thus, the difference arises from the inclusion of $p_{\text {sil }}^{\text {trawl }}=\frac{T_{s j l}}{\sum_{l} T_{s j l}}$ in the alternative method.

Comparing the proportion-at-age using data from different parts of the survey area
Tables 1a to 1 k show the proportion-at-age calculated using the three options of combining the length frequency and age-length-key. There is no difference in the proportions-at-age calculated using methods I) and III) and the difference between methods I) and II) is minor.

## Discussion

Although the past 'mismatch' between the survey area used for the length frequency and age-length-key used to calculate the November survey proportions-at-age (option III)) has not proved to result in a large difference in the results had data up to Port Alfred only been used, we recommend that for self-consistency, the November survey proportions-at-age be calculated using the length frequency together with the age-length-key using data up to Port Alfred only.

## Way Forward

In order to test the effect of weighting the trawls independently of the acoustic weighting, two further methods will be tested:
i) an "equal weighting" method in which all trawls are weighted equally. In this case, the weighting factor becomes $w_{s j}=\frac{1}{n_{s}}$ where $n_{s}$ is the number of trawls in the stratum and therefore equation (B.7) changes to:

$$
p_{s l}=\sum_{j} p_{s j l}^{t r a w l} \cdot \frac{1}{n_{s}}
$$

ii) a "down weighted" method in which small trawl sub-samples are downweighted. Although scientists aim to sample 100 fish from each trawl (Coetzee pers comm.), the actual number of fish sub-sampled can vary considerably (Figure 1). As 100 fish is currently used as a 'cut-off' when sampling, the weighting factor remains $w_{s j}=\frac{1}{n_{s}}$ if $T_{s, j}>100$, but is $w_{s j}=\frac{T_{s, j}}{100 * n_{s}}$ if $T_{s, j} \leq 100$.

The median and standard deviations around the proportions-at-age and proportions-at-length from these two further methods will be compared to the alternative method to investigate the effect the chosen method of weighting has on the median proportions, and in particular the standard deviations.

## Acknowledgements

We thank Janet Coetzee for providing the current method used to weight the length frequencies and for comments on earlier parts of this work.

## Appendix A: The Current Method Used to Calculate the Weighted Length Frequencies

The acoustic weighting for each trawl sample $j$ in stratum $s$ is given by:

$$
\begin{equation*}
Z_{s j}=\sum_{i} L_{s j i} \cdot \rho_{s j i} \tag{A.1}
\end{equation*}
$$

where
$L_{s j i} \quad$ is the mean interval length (nmi) for trawl sample $j$ and interval (ESDU) $i$ in stratum $s$, and
$\rho_{s j i} \quad$ is the mean acoustic interval density ( $\mathrm{g} \cdot \mathrm{m}^{-2}$ ) for trawl sample $j$ and interval (ESDU) $i$ in stratum $s$.

To weigh individual trawls, one needs to convert the acoustic weighting factor into a factor in terms of numbers. The trawl weighting factor is given by:

$$
\begin{equation*}
Q_{s j}=\frac{Z_{s j}}{W_{s j}} \tag{A.2}
\end{equation*}
$$

where
$W_{s j} \quad$ is the total mass ( kg ) (also termed length frequency mass) of all the fish in the sub-sample from trawl $j$ in stratum $s$.

The weighted length frequency in stratum $s$ is the vector $\mathbf{T}_{s}$, which has elements

$$
\begin{equation*}
T_{s l}=\sum_{j} T_{s j l} \cdot Q_{s j} \tag{A.3}
\end{equation*}
$$

where
$T_{s j l} \quad$ is the number of fish of length $l$ in the sub-sample from trawl $j$ in stratum $s$.

The total number of fish of length $l$ estimated by the survey to be in stratum $s$ is then given by:

$$
\begin{equation*}
N_{s l}=\frac{T_{s l} \cdot B_{s}}{\sum_{j} Z_{s j}} \tag{A.4}
\end{equation*}
$$

where
$B_{s} \quad$ is the biomass $(\mathrm{kg})$ in stratum $s$.

The total number of fish of length $l$ estimated by the survey is then given by:

$$
\begin{equation*}
N_{l}^{t o t}=\sum_{s} N_{s l} \tag{A.5}
\end{equation*}
$$

## Appendix B: The Alternative Method to Calculate the Weighted Length Frequencies

The acoustic weighting for each trawl sample $j$ in stratum $s$ is given by:

$$
\begin{equation*}
Z_{s j}=\sum_{i} L_{s j i} \cdot \rho_{s j i} \tag{B.1}
\end{equation*}
$$

where
$L_{s j i} \quad$ is the mean interval length (nmi) for trawl sample $j$ and interval (ESDU) $i$ in stratum $s$, and $\rho_{s i i} \quad$ is the mean acoustic interval density ( $\mathrm{g} . \mathrm{m}^{-2}$ ) for trawl sample $j$ and interval (ESDU) $i$ in stratum $s$.

From the total number of fish of all species sampled from a trawl, a sub-sample of a species of interest is drawn for the purposes of estimating length distribution. The total number of fish in this sub-sample from trawl $j$ in stratum $s$ is given by:

$$
\begin{equation*}
T_{s j}=\sum_{l} T_{s j l} \tag{B.2}
\end{equation*}
$$

where
$T_{s j l} \quad$ is the number of fish of length $l$ in the sub-sample from trawl $j$ in stratum $s$.

The mean mass ( kg ) of an individual fish in the sub-sample from trawl $j$ in stratum $s$ is given by:

$$
\begin{equation*}
\bar{W}_{s j}=\frac{W_{s j}}{T_{s j}} \tag{B.3}
\end{equation*}
$$

where
$W_{s j} \quad$ is the total mass $(\mathrm{kg})$ of all the fish in the sub-sample from trawl $j$ in stratum $s$.

The number of fish estimated by the survey to be in stratum $s$ that are associated with trawl $j$ is then given by:

$$
\begin{equation*}
N_{s j}=\frac{k_{s} \cdot Z_{s j}}{\bar{W}_{s j}} \tag{B.4}
\end{equation*}
$$

where $k_{s}=\frac{B_{s}}{\sum_{j} Z_{s j}}$ is the conversion factor (in kgs) which relates the estimate of biomass for the stratum, $B_{s}$
(NB: in kgs) to the sum of the acoustic weights.

The total number of fish estimated by the survey to be in stratum $s$ is then calculated as follows:

$$
\begin{equation*}
N_{s}=\sum_{j} N_{s j}=k_{s} \sum_{j} \frac{Z_{s j}}{\overline{W_{s j}}} \tag{B.5}
\end{equation*}
$$

The proportion of fish of length $l$ in the sub-sample from trawl $j$ in stratum $s$ is then given by:

$$
\begin{equation*}
p_{s j l}^{\text {trawl }}=\frac{T_{s j l}}{\sum_{l} T_{s j l}} \tag{B.6}
\end{equation*}
$$

and the proportion of all the fish of length $l$ in stratum $s$ is then estimated as:

$$
\begin{equation*}
p_{s l}=\sum_{j} p_{s j l}^{\text {trawl }} \cdot \frac{N_{s j}}{N_{s}} \tag{B.7}
\end{equation*}
$$

In this context, therefore, the proportion of fish of length $l$ in stratum $s$ is estimated from the proportion of fish of length $l$ in the sub-samples taken from each trawl $j$ in the stratum, weighted by the proportion of the total number of fish estimated to be in that stratum which is associated with trawl $j$, i.e. $w_{s j}=\frac{N_{s j}}{N_{s}}$.

The estimated number of fish of length $l$ in stratum $s$ is therefore

$$
\begin{equation*}
N_{s l}=p_{s l} \cdot N_{s}=\left(\sum_{j} p_{s j l}^{\text {trawl }} \cdot \frac{N_{s j}}{N_{s}}\right) \cdot N_{s}=\sum_{j} p_{s j l}^{\text {trawl }} N_{s j} \tag{B.8}
\end{equation*}
$$

and the estimated total number of fish of length $l$ in the complete area surveyed is given by:

$$
\begin{equation*}
N_{l}^{t o t}=\sum_{s} N_{s l} \tag{B.9}
\end{equation*}
$$

## Appendix C: The Calculation of the Proportion-at-Age in the Survey, given the Length Frequency

The estimated total number of fish of age $a$ in length class $l$ in the complete area surveyed is given by:

$$
\begin{equation*}
N_{l a}=\frac{n_{l a}}{\sum_{a} n_{l a}} N_{l}^{t o t} \tag{C.1}
\end{equation*}
$$

where
$n_{l a} \quad$ is the number of otoliths in length class $l$ allocated to age $a$.

The estimated proportion by age of the total number in the complete area surveyed is then given by

$$
\begin{equation*}
p_{a}=\frac{\sum_{l} N_{l a}}{\sum_{a} \sum_{l} N_{l a}} . \tag{C.2}
\end{equation*}
$$

## Appendix D: Bootstrapping

For $b=1, \ldots, 1000$ resample with replacement the sets of data $\left(Z_{s j}^{b}, W_{s j}^{b}, T_{s j l}^{b}{ }_{l=4, \ldots, 23}\right.$ ) as used in equation (C.1), (C.2) and (C.3) above ${ }^{2}$.

As before, the total number of fish in this sub-sample from trawl $j$ in stratum $s$ is given by:

$$
\begin{equation*}
T_{s j}^{b}=\sum_{l} T_{s j l}^{b} \tag{D.1}
\end{equation*}
$$

The mean mass ( kg ) of an individual fish in the sub-sample from $\operatorname{trawl} j$ in stratum $s$ is given by:

$$
\begin{equation*}
\bar{W}_{s j}^{b}=\frac{W_{s j}^{b}}{T_{s j}^{b}} \tag{D.2}
\end{equation*}
$$

The number of fish estimated by the survey to be in stratum $s$ that are associated with trawl $j$ is then given by:

$$
\begin{equation*}
N_{s j}^{b}=\frac{k_{s}^{b} \cdot Z_{s j}^{b}}{\bar{W}_{s j}^{b}} \tag{D.3}
\end{equation*}
$$

where $k_{s}^{b}=\frac{B_{s}}{\sum_{j} Z_{s j}^{b}}$ is the conversion factor (in kgs) which relates the estimate of biomass for the stratum, $B_{s}$ (NB: in kgs) to the sum of the acoustic weights.

The total number of fish estimated by the survey to be in stratum $s$ is then calculated as follows:

$$
\begin{equation*}
N_{s}^{b}=\sum_{j} N_{s j}^{b}=k_{s}^{b} \sum_{j} \frac{Z_{s j}^{b}}{\bar{W}_{s j}^{b}} \tag{D.4}
\end{equation*}
$$

The proportion of fish of length $l$ in the sub-sample from trawl $j$ in stratum $s$ is then given by:

$$
\begin{equation*}
p_{s i l}^{t r a w l, b}=\frac{T_{s j l}^{b}}{\sum_{l} T_{s j l}^{b}} \tag{D.5}
\end{equation*}
$$

and the proportion of all the fish of length $l$ in stratum $s$ is then estimated as:

$$
\begin{equation*}
p_{s l}^{b}=\sum_{j} p_{s j l}^{t r a w l, b} \cdot \frac{N_{s j}^{b}}{N_{s}^{b}} \tag{D.6}
\end{equation*}
$$

The estimated number of fish of length $l$ in stratum $s$ is therefore

$$
\begin{equation*}
N_{s l}^{b}=p_{s l}^{b} \cdot N_{s}^{b} \tag{D.7}
\end{equation*}
$$

and the estimated total number of fish of length $l$ in the complete area surveyed is given by:

$$
\begin{equation*}
N_{l}^{\text {tot }, b}=\sum_{s} N_{s l}^{b} \tag{D.8}
\end{equation*}
$$

The estimated total number of fish of age $a$ in length class $l$ in the complete area surveyed is given by:

[^2]\[

$$
\begin{equation*}
N_{l a}^{b}=\frac{n_{l a}}{\sum_{a} n_{l a}} N_{l}^{t o t, b} \tag{D.9}
\end{equation*}
$$

\]

and the estimated proportion by age of the total number in the complete area surveyed is then given by

$$
\begin{equation*}
p_{a}^{b}=\frac{\sum_{l} N_{l a}^{b}}{\sum_{a} \sum_{l} N_{l a}^{b}} . \tag{D.10}
\end{equation*}
$$

[^1]:    ${ }^{1}$ The bootstrapped CV is calculated as (Boostrapped Average)/(Bootstrapped SD).

[^2]:    ${ }^{2}$ Thus if there were originally $n$ trawls in stratum $s$, then $j=1 \ldots n$ sets of data are resampled with replacement from the trawls of stratum $s$.
