# Proposed Reference Set for the South African hake resource to be used in OMP-2010 testing 

Rebecca A Rademeyer and Doug S Butterworth

February 2010

#### Abstract

SUMMARY A Reference Set (RS) of 12 scenarios is put forward as the primary basis to be used to simulation test candidates for the revised OMP for hake, OMP-2010. The principal uncertainty axes spanned by this RS are the central year for the switch from a primarily $M$. capensis to a primarily M. paradoxus fishery, values for natural mortality at age, and the form of the stock-recruitment relationship. The various data sets are generally reasonably fitted by these models, with the recent GLM-standardised CPUE series having the greatest influence.

## INTRODUCTION

The principal aim of this paper is to present a set of assessments which are proposed to provide the Operating Models (OMs) to form a Reference Set (RS) to be used for testing a revised OMP for the hake resource (OMP-2010), which is due for adoption in September 2010.

Appendix I details the data used in these analyses, while the specifications and equations of the OMs are set out in Appendix II.

The following changes have been made to the Reference Case presented in Rademeyer and Butterworth (2009). These and related results presented further below take account of pertinent recommendations by the External Panel at the December 2009 international stock assessment workshop (specifically A.4, A.5, A.12, A.15, A. 16 and A.18) (Punt et al., 2009)..

1) An error in the code has been corrected.
2) The maturity-at-length for males, which was previously taken to be the same as the female maturity-at-length, has been updated to conform with the most recently available information (Fairweather, pers. commn).
3) The selectivities-at-age have been renormalized across the genders and not for each gender.
4) The standard deviations of length-at-age $\theta_{a}$ had been estimated directly for each of the ages 0 to 7 , but hit an upper bound for ages 1 to 7 . Furthermore, $\theta_{a}$ was not species and gender specific. $\theta_{0}$ is now estimated directly for each species and gender, and for ages 1 and above a linear relationship is assumed: $\theta_{a}=\alpha+\beta a$, with species and gender-specific $\alpha$ and $\beta$ estimated in the model fitting procedure.
5) The length-at-age distributions are assumed to follow a log-normal distribution rather than a normal distribution, as plots of these data were indicative of skew distributions.
6) The most recently available GLM-standardised CPUE series are used (Glazer, 2009), together with the associated updated species-split offshore trawl catches..
7) The centre year of the shift from a primarily M. capensis to a primarily M. paradoxus offshore trawl catch is taken as either 1950, 1958 or 1965, instead of 1950 only.
8) The recruitment variability parameter $\sigma_{R}=0.45$ instead of 0.25 ( $\sigma_{R}$ is still taken to decrease from this value to 0.1 over the last five years to statistically stabilise estimates of recent recruitment)..
9) The south coast offshore trawl scaling factor for the female M. paradoxus selectivity is taken as the average of the scaling factors estimated for the south coast spring and autumn surveys rather than being estimated directly, as the available data scarcely seem sufficient for such independent estimation..
10) The age-composition data (age-length keys - ALKs) used in the assessment have been restricted to one reading only for each otoliths (see Appendix I, section I.4). Furthermore, three sets of $M$. paradoxus age-length keys, which reflected many low ages at rather large lengths, have been omitted because they were inconsistent with the other sets. These are: i) 1997 West Coast summer survey, ii) 2004 West Coast summer and iii) 2006 West Coast summer data sets. (see Fig. App.I.5).
11) After the ALKs had been restricted to one reading only for each otolith, outliers were removed by excluding data outside (mean - 3SD; mean +3 SD). The means and SDs for each age were computed across all the data for each species. Less than $1 \%$ of these data were excluded for each species in this process.
12) The ALK likelihood downweighting factor was increased to 0.01 (from 0.001 ) as fits indicated an apparent lack of influence (underweighting).
13) A penalty has been added to $-\ln \mathrm{L}$ to constrain the survey $q$ 's for each species not to exceed 1 (see equation App.II.34); this amounts to the assumption that there is no substantial herding effect which is biasing the swept-area estimates of abundance from these trawl surveys, and precludes survey abundance estimates from (on average) exceeding the underlying available biomass.
14) Previously, different selectivity slopes at large lengths/ages were freely estimated for the second (1977-1984) and third (1993-2009) selectivity period for the offshore trawl fleet. However fitting always preferred a lower slope for the earlier years, which seems inconsistent with the movement of the fleet towards deeper waters (where larger hake are available) over time. Thus the slope for the second period was constrained not to be lower than that for the third.
15) A penalty was added to $-\ln L$ so that the mean of the estimated recruitment residuals is close to zero (see equation App.II.43). The reason for this is that fits to the last some 30 years for which these residuals could be estimated generally showed averages appreciably below zero for $M$. capensis. If such fits had been taken through to projections, this would have meant that immediate future recruitment for M. capensis would have been higher on average than over recent years, thus giving a likely spuriously positive impression of resource production. It was felt more appropriate to force this average level of future production to be similar to that over the past three decades. While the possibility that those decades constitute a regime of generally low M. capensis productivity cannot be excluded, the associated effective changes in $K$ are considered better reserved for robustness tests.

## RESULTS

## Reference Set

The proposed Reference Set (RS) consists of 12 cases, detailed in Table 1. These 12 cases vary their choices of factors along three axes that contribute most variability to assessment results:
a) the centre year of the shift from a primarily M. capensis to a primarily M. paradoxus offshore trawl catch (1950, 1958 or 1965);
b) natural mortality at age specifications; and
c) the stock-recruitment relationship (Beverton-Holt with steepness $h$ estimated or fixed, or modified Ricker with $\gamma$ estimated - see equations App.II.4a,b).
The primary design intended a full cross of 2 centre-years x 2 natural mortality vectors $\times 3$ stock recruitment relationships, or 12 scenarios in all, but subject to the constraint that a fit with a $-\operatorname{lnL}$ difference of more than about 15 from that for the best of the fits would be excluded on the basis of poor compatibility with the data. (Of course, in strict likelihood terms such a large difference implies enormously different relative likelihoods across these scenarios, but that would be over-interpreting the likelihood function used here which has not attempted to take full account of non-independence amongst the data fitted.)

With the Beverton-Holt fits indicating estimates of steepness $h$ at its upper bound of 0.98 , it was considered important to include scenarios with lower values of $h$ in the RS to admit greater possibilities of recruitment overfishing taking place, but the $-\ln L$ difference constraint excluded three of the associated four scenarios, leaving only RS10 amongst the RS.

Attempts to freely fit natural mortality at age vectors led to widely varying results from scenario to scenario, so it was considered best to fix two vectors which arguably span the plausible range: a high $M$ scenario of $M_{2}=0.9, M_{5}=0.5$. and a low $M$ scenario of $M_{2}=0.6, M_{5}=0.25$. The primary RS runs combined either both high $M s$ or both low $M$ s for the two species, M. paradoxus and M. capensis. Scenarios which crossed high and low $M$ values across the two species were also investigated, but mainly found to fail to meet the - lnL difference criterion. However, one exception to this was a scenario (RS11) with both a good fit to the data and a qualitatively different trajectory for M. capensis (reflecting a rather more heavily depleted M. capensis resource than do the other scenarios). It is considered important to retain this in the RS, together with a variant with slightly different specifications of natural mortality at age for M. capensis (RS12) which also showed this different trajectory behaviour for M. capensis. In subsequent presentation of candidate OMP results, the RS will be split into two: RSa (RS1 to RS10) and RSb (RS11 to RS12), so as not to mix results across qualitatively different $M$. capensis trajectories.
The RS is completed by a "central" Reference Case (RC) scenario, corresponding to a mid-year choice for the shift from a primarily $M$. capensis to $M$. paradoxus fishery, and an average of the two $M$ vectors for natural mortality at age. The modified Ricker was preferred to the Beverton-Holt stock recruitment relationship for this scenario because it tends to yield slightly better fits to the data. Most robustness tests are single factor variants of this RC. A detailed set of results for the RC, showing fits to all the input data, is given in Appendix III.

Table 2 summarises the key management quantity estimates across the RS, while Table 3 compares the different contributions to the total negative log-likelihood.
Fig. 1 plots the estimated spawning biomass trajectories for the RS. Fig. 2 shows their fits to the CPUE series. Only the CPUE series fits have been shown here, because as is evident from Table 3 it is fits to the CPUE, and particularly the more recent GLM-CPUE series, that are the main determinants of the overall likelihood of the scenario.

A matter that remains to be discussed is whether scenario RS4 should remain within the RS as proposed. While it is a member of the set provided by the cross of the dominant uncertainty factors, it does not meet the $-\operatorname{lnL}$ difference criterion.

## Robustness tests

Table 4 details the robustness/sensitivity tests conducted to date. (Some of these tests should be considered as "sensitivities" rather than formal robustness tests to provide OMs for candidate OMP testing, because they are included more to indicate impacts of specification variation on results than as arguably alternative plausible representations of reality.)

Table 5 summarises the key management quantities for these robustness/sensitivity tests, while Table 6 compares their different contributions to the total negative log-likelihood.

Fig. 3 plots the estimated spawning biomass trajectories for these further tests.
Table 7 lists robustness tests which are still planned to be run.

## DISCUSSION

Experience with implementation of the assessment methodology has led to some changes in the details of the Reference Set of OMs suggested in the December 2009 Expert Panel report (Punt et al., 2009). Specifically statistical stability considerations dictated a different approach to handling alternative natural mortality schedules, and a lesser range of steepness than suggested earlier was necessitated because of otherwise large reductions in the likelihoods of the model fits to the data. However, the somewhat better fits obtained using a modified Ricker stock recruitment relationship in place of the Beverton-Holt led to including that form in the proposed RS.
The range for choices of the central year for the shift from a primarily M. capensis to primarily $M$. paradoxus trawl fishery was extended back to 1950, given the somewhat better likelihoods obtained for choices of earlier years for this parameter, though this basis for preferring earlier years does not seem as strong as in the past. Trends in catchability have yet to be considered, but the effect of such trends noted earlier (a more depleted M. capensis resource) are already captured by scenarios RS11 and RS12.

Fixing rather than estimating selectivity slopes at large lengths/ages has yet to be fully explored, though initial results suggest a large deterioration in the likelihood of the fits.
Scenarios with the lower value of 0.25 for $M_{5+}$ often lead to arguably unrealistically high pristine spawning biomass values. These can however be reduced, with little impact on other important management-related variables, by postulating an increase in natural mortality at higher ages (detailed results for this possibility will be reported in due course).
Fits of the assessment model to the data are generally good. From Tables 3 and 6 it is evident that fits to the CPUE data and to the commercial catches-at-length are the primary determinants of the overall likelihood. The more recent GLM-standardised CPUE plays the greatest role, particularly for $M$. paradoxus where many of the model variants have some difficulty in matching the earliest and the very recent values.

The primary consideration in proposing a RS is that its component OMs should span most of the range of plausible possibilities for the underlying dynamics. Table 2 suggests that this criterion is reasonably satisfied for M. paradoxus depletion and productivity (reflected by MSY). There is lesser variability amongst the RSa depletion estimates for M. capensis, but the scenarios in RSb would seem adequate to cover the possibility that the RSa depletion estimates are misleading.
The robustness/sensitivity tests completed to date (Tables 4-6) broadly do not lead to stock status and dynamics estimates outside the range covered by the proposed RS, so that this proposed RS would seem adequate to provide the primary basis upon which to simulation test candidates for OMP-2010.

## APPENDIX I - The Data Utilized

## I. 1 Annual catches

The species-split of the catches is carried out external to the model. A summary of the assumptions made to disaggregate the catches by species for the Reference Set is given below. The reported or assumed catches by fleet and species are given in Table App.I. 1 and plotted in Fig. App.I.1.

## Offshore trawl fleet

From 1978 onwards, the catches made by the offshore trawl fleet have been split by species by applying the size-based species proportion-by-depth relationships for the west and south coasts which were updated by Gaylard and Bergh (2009) from research survey data.
Prior to 1978, there is no depth information recorded for the landings so that the proportion of $M$. capensis caught cannot be estimated using the method above. The catch data for the 1917-1977 period are split by assuming that the proportion of M. capensis caught follows a logistic function over this period, starting at 1 and then decreasing to stabilise at the 1978-1982 average value. As trawling was concentrated in inshore areas around Cape Town and to the east when the fishery began (i.e. probably catching M. capensis exclusively) and progressively moved offshore, this seems a more defensible approach. To reflect a change from a M. capensis only fishery to the species ratio in the catch in 1978, the changing proportion with year $y$ of M. capensis in the offshore trawl catch on coast $c$ is modelled by:

$$
\begin{equation*}
\text { prop }_{c y}^{\text {prop }}=\frac{1-\Delta_{c}}{1+\exp \left[\left(y-P_{1}\right) / P_{2}\right]}+\Delta_{c} \tag{App.I.1}
\end{equation*}
$$

where
$\Delta_{c} \quad$ is the average proportion of M. capensis in the offshore catch over the 1978-1982 period for coast $c(24 \%$ and $60 \%$ for the west and south coasts respectively), and
$P_{1}, P_{2} \quad$ are parameters of the logistic function; $P_{1}$ is the year in which the proportion of $M$. capensis in the catch is mid-way between $100 \%$ and $\Delta_{c}$, while $P_{2}$ determines how rapidly this change in proportion occurs.

The RS' OMs assume either $P_{I}=1950,1958$ or 1965 and $P_{2}=1.5$.

## Inshore trawl and handline fleets

Catches made by these fleets are assumed to consist of M. capensis only, as they operate in relatively shallow water on the south coast.

## Longline fleet

Longline catches on the west coast are assumed to consist of $30 \%$ M. capensis for the whole period, while on the south coast, catches by this fleet are assumed to consist of M. capensis exclusively (Andrew Penney, PISCES, pers. commn).

The total catch in 2009 is assumed equal to the TAC for that year (118 600 t ); it is split between the different fleets and species assuming the same proportions as in 2008.

## I. 2 Abundance indices

Six CPUE time-series are available for assessing the status of the resource (Table App.I.2): a CPUE series for each of the south and west coasts developed by the International Commission for South East Atlantic Fisheries (ICSEAF, 1989) and a GLM-standardised CPUE series for each coast, for each of $M$. paradoxus and M. capensis (Table App.I.2) from the offshore trawl fleet (Glazer, 2009). The two historical CPUE series cannot be disaggregated by species, as there are no effort-by-depth data available for this pre-1978 period. The GLM standardized CPUE indices are species-specific (the catch data being based on the Gaylard and Bergh (2009) algorithm).

Research surveys have been conducted on board the FRS Africana from 1986 in spring and/or autumn on the south coast and from 1985 in summer and/or winter on the west coast, and provide fully speciesspecific information. Since 2003, new fishing gear has occasionally been used on the Africana, for which a calibration factor is available. Survey biomass estimates and their estimated (sampling) standard errors are listed in Tables App.I.3-4 (Fairweather, 2009). Only surveys extending to the deepest depth ( 500 m ) normally included in the survey design are considered for reasons of comparability.

The surveys conducted on the West Coast in 2000 and 2001 by the Nansen research vessel have not been used in this analysis. As no calibration experiments were conducted at the time, these would have to be considered as a separate series and with only two data points would not be informative.

## I. 3 Length frequencies

Survey length frequencies are available disaggregated by species and in some years disaggregated by gender (Table App.I.5) (Fairweather et al., 2009).

Sex-aggregated proportions-at-length for each survey stratum ( $p_{y l}^{s u r v, i}$ ) are provided in 1 cm length classes (Fairweather et al., 2009). In some instances, the proportions of males and females for a particular survey stratum and length class are available $\left(q_{y l}^{g, \text { surv,i}}\right.$, where $\left.\sum_{g} q_{y l}^{g, \text { surv,i}}=1\right)$. These are converted to survey specific (i.e. aggregated over all strata for a particular cruise) proportions-atlengths for males $(g=1)$, females $(g=2)$ and unsexed $(g=0)$ (with $\sum_{g=0}^{2} p_{y l}^{g, \text { surv,i}}=1$ ) as follows:
The proportions-at-length are grouped into 2 cm length classes.
a. For all length classes $<21 \mathrm{~cm}$, the proportions-at-length are assumed to be unsexed;
b. For length classes $>20 \mathrm{~cm}$ :

- If there is no sex-information for either of the two 1 cm length classes to group (i.e. $\sum_{g} q_{y l}^{g, s u r v, i}=0$ and $\sum_{g} q_{y, l+1}^{g, s u r v, i}=0$ ), then the proportion for the resulting 2 cm length class is assumed to be unsexed:

$$
p_{y L}^{g, s u r v, i}=\left\{\begin{array}{cc}
p_{y l}^{s u r v, i}+p_{y, l+1}^{s u r v, i} & \text { for } g=0  \tag{App.I.1}\\
0 & \text { for } g=1 / 2
\end{array}\right.
$$

- If there is sex-information for one of the two 1 cm length classes to group (i.e. if $\sum_{g} q_{y l}^{g, \text { surv,i}}=1$ or $\sum_{g} q_{y, l+1}^{g, s u r v, i}=1$ ), then the sex-information from the one length class is used for both:

$$
p_{y L}^{g, \text { surv }, i}=\left\{\begin{array}{cc}
0 & \text { for } g=0  \tag{App.I.2}\\
q_{y l}^{g, s u r v, i}\left(p_{y l}^{\text {surv }, i}+p_{y, l+1}^{\text {surv,i}}\right) & \text { for } g=1 / 2
\end{array}\right.
$$

- If there is sex-information for both of the two 1 cm length classes to group (i.e. if $\sum_{g} q_{y l}^{g, \text { surv }, i}=1$ and $\left.\sum_{g} q_{y, l+1}^{g, \text { surv }, i}=1\right)$, then the sex-information is used directly:

$$
p_{y L}^{g, \text { surv, }, i}=\left\{\begin{array}{cc}
0 & \text { for } g=0  \tag{App.I.3}\\
q_{y l}^{g, s u r v, i} p_{y l}^{s u r v, i}+q_{y, l+1}^{g, s u r v, i} p_{y, l+1}^{s u r v, i} & \text { for } g=1 / 2
\end{array}\right.
$$

c. The strata proportions-at-length are weighted by the estimated total number in the strata to obtain a survey specific gender-disaggregated proportions-at-length ( $p_{y l}^{g, \text { surv }}$ ). The estimated total number in each stratum is calculated as:

$$
\begin{equation*}
N_{y}^{s u r v, i}=B_{y}^{s u r v, i} / \bar{W}_{y}^{s u r v, i} \tag{App.I.4}
\end{equation*}
$$

where
$B_{y}^{s u r v, i}$ is the survey biomass estimate for stratum $i$ in survey surv, and
$\bar{W}_{y}{ }^{\text {surv,i}}$ is the mean weight of fish for stratum $i$ in survey surv, with

$$
\begin{equation*}
\bar{W}_{y}^{s u r v, i}=\sum_{l}\left(p_{y l}^{s u r v, i} \alpha l^{\beta}\right) \tag{App.I.5}
\end{equation*}
$$

d. For each 2 cm length class, if the unsexed proportion is less than $20 \%$ of the total proportion in that length class, the sexed proportion is used to split the unsexed proportion into males and females.

Figs. App.I.2-3 plot the survey length frequencies available.
Length frequency information from the commercial catch is not available by species, the reason being that it is often based on cleaned (headed and gutted) fish, which cannot be easily identified by species. As a result it is not possible to disaggregate the commercial length frequencies by species. Commercial catches-at-length for the offshore and for the inshore and longline fleets are shown in Tables App.II.1012. The south coast inshore and longline fleet catches are assumed to consist of M. capensis only.

## I. 4 Age-Length Keys

Table App.I. 6 lists the age-length keys available. Data from animals with frills on gills (FOG) have been discarded ( $<3 \%$ of the total). All aged animals less or equal to 20 cm in length are assumed to be juveniles, i.e. of unknown gender. The few unsexed data from animals greater than 20 cm have been discarded ( $<1 \%$ of the total), as well as the outliers, defined as the data points lying outside the mean $\pm 3 \mathrm{~s} . \mathrm{d}$. for each age (mean and s.d. calculated across all years and surveys). Three ALKs for $M$. paradoxus have been totally ignored in the model fitting as they seemed inconsistent with the other ALKs: i) 1997 West Coast summer survey, ii) 2004 West Coast summer and iii) 2006 West Coast summer. The data for these three sets are shown in Fig. App.I.5.

Most otoliths are read more than once, however only one reading for each otoliths is used in the fitting procedure. Table App.I. 7 show which reader was selected in the event of more than one reading.

Table App.I.1: Species-disaggregated catches (in thousand tons) of South African hake from the south and west coasts (see text for details), assuming 1958 as the centre year of the shift from a primarily $M$. capensis to a primarily $M$. paradoxus offshore trawl catch.

## APPENDIX II - Gender-disaggregated, Age-Structured Production Model fitting to Age-Length Keys

The model used is a gender-disaggregated Age-Structured Production Model (ASPM), which is fitted directly to age-length keys (ALKs) and length frequencies. The model also involves assessing the two species as two independent stocks and is fitted to species-disaggregated data as well as speciescombined data. The general specifications and equations of the overall model are set out below together with some key choices in the implementation of the methodology. Details of the contributions to the log-likelihood function from the different data considered are also given. Quasi-Newton minimisation is used to minimise the total negative log-likelihood function (implemented using AD Model Builder ${ }^{\mathrm{TM}}$, Otter Research, Ltd.).

## Population Dynamics

## Numbers-at-age

The resource dynamics of the two populations (M. capensis and M. paradoxus) of the South African hake are modelled by the following set of equations:

Note: for ease of reading, the 'species' subscript $s$ has been omitted below where not relevant.

$$
\begin{aligned}
& N_{y+1,0}^{g}=R_{y+1}^{g} \\
& N_{y+1, a+1}^{g}=\left(N_{y a}^{g} e^{-M_{a}^{g} / 2}-\sum_{f} C_{f y a}^{g}\right) e^{-M_{a}^{g} / 2} \quad \text { for } 0 \leq a \leq m-2 \\
& N_{y+1, m}^{g}=\left(N_{y, m-1}^{g} e^{-M_{m-1}^{g} / 2}-\sum_{f} C_{f, y, m-1}^{g}\right) e^{-M_{m-1}^{g} / 2}+\left(N_{y m}^{g} e^{-M_{m}^{g} / 2}-\sum_{f} C_{f y m}^{g}\right) e^{-M_{m}^{g} / 2} \text { (App.II.3) }
\end{aligned}
$$

where
$N_{y a}^{g} \quad$ is the number of fish of gender $g$ and age $a$ at the start of year $y^{l}$,
$R_{y}^{g} \quad$ is the recruitment (number of 0-year-old fish) of fish of gender $g$ at the start of year $y$,
$m \quad$ is the maximum age considered (taken to be a plus-group),
$M_{a}^{g}$ denotes the natural mortality rate on fish of gender $g$ and age $a$, and
$C_{f y a}^{g} \quad$ is the number of hake of gender $g$ and age $a$ caught in year $y$ by fleet $f$.

## Recruitment

The number of recruits (i.e. new zero-year old fish) at the start of year $y$ is assumed to be related to the corresponding female spawning stock size (i.e., the biomass of mature female fish) by means of the Beverton-Holt (Beverton and Holt, 1957) or a modified (generalised) form of the Ricker stockrecruitment relationship, parameterized in terms of the "steepness" of the stock-recruitment relationship, $h$, and the pre-exploitation equilibrium female spawning biomass, $K^{\circ} s p$, and preexploitation recruitment, $R_{0}$ and assuming a $50: 50$ sex-split at recruitment.

[^1]$R_{y}^{g}=\frac{4 h R_{0} B_{y}^{\rho, s p}}{K^{\rho, s p}(1-h)+(5 h-1) B_{y}^{\rho, s p}} e^{\left(\varsigma_{y}-\sigma_{R}^{2} / 2\right)}$
(App.II.4a)
for the Beverton-Holt stock-recruitment relationship and
$R_{y}^{g}=\alpha B_{y}^{\rho, s p} \exp \left(-\beta\left(B_{y}^{\rho, s p}\right)^{\gamma}\right) e^{\left(\varsigma_{y}-\sigma_{R}^{2} / 2\right)}$
(App.II.4b)
with
$\alpha=R_{0} \exp \left(\beta\left(K^{\circ, s p}\right)^{\gamma}\right) \quad$ and $\quad \beta=\frac{\ln (5 h)}{\left(K^{\circ, s p}\right)^{\gamma}\left(1-5^{-\gamma}\right)}$
for the modified Ricker relationship (for the true Ricker, $\gamma=1$ ) where
$\varsigma_{y} \quad$ reflects fluctuation about the expected recruitment in year $y$;
$B_{y}^{+s p} \quad$ is the female spawning biomass at the start of year $y$, computed as:
$B_{y}^{\ominus, s p}=\sum_{a=1}^{m} f_{a}^{\odot} w_{a}^{\odot} N_{y a}^{\odot}$
(App.II.5)
where
$w_{a}^{g} \quad$ is the begin-year mass of fish of gender $g$ and age $a$;
$f_{a}^{g} \quad$ is the proportion of fish of gender $g$ and age $a$ that are mature; and
$. R_{0}=K^{\circ}, s p /\left[\sum_{a=1}^{m-1} f_{a}^{\circ} w_{a}^{\circ} e^{-\sum_{a=0}^{a-1} M_{a^{\prime}}^{g}}+f_{m}^{\circ} w_{m}^{\circ} \frac{e^{-\sum_{a=0}^{m-1} M_{a^{\prime}}^{g}}}{1-e^{-M_{m}^{g}}}\right]$
(App.II.6)

For the Beverton-Holt form, $h$ is bounded above by 0.98 to preclude high recruitment at extremely low spawning biomass, whereas for the modified Ricker form, $h$ is bounded above by 1.5 to preclude extreme compensatory behaviour.
Total catch and catches-at-age
The fleet-disaggregated catch by mass, in year $y$ is given by:
$C_{f y}=\sum_{g} \sum_{a=0}^{m} w_{a+1 / 2}^{g} C_{f y a}^{g}=\sum_{g} \sum_{a=0}^{m} w_{a+1 / 2}^{g} N_{y a}^{g} e^{-M_{a}^{g} / 2} F_{f y} \tilde{S}_{f y a}^{g}$
(App.II.7)
where
$C_{f y a}^{g}$ is the catch-at-age, i.e. the number of fish of gender $g$ and age $a$, caught in year $y$ by fleet $f$;
$F_{f y} \quad$ is the fishing mortality of a fully selected age class, for fleet $f$ in year $y$ (independent of $g$ );
$\tilde{S}_{f y a}^{g}=\tilde{w}_{f y, a+1 / 2}^{g} / w_{a+1 / 2}^{g}$
(App.II.8)
$\tilde{S}_{f y a}^{g} \quad$ is the effective commercial selectivity of gender $g$ at age $a$ for fleet $f$ and year $y$; with

$$
\widetilde{w}_{f y, a+1 / 2}^{g}=\sum_{l} S_{f y l}^{g} w_{l}^{g} P_{a+1 / 2, l}^{g}
$$

(App.II.9)
$\widetilde{w}_{f y, a+1 / 2}^{g}$ is the selectivity-weighted mid-year weight-at-age $a$ of gender $g$ for fleet $f$ and year $y$;
$w_{l}^{g} \quad$ is the weight of fish of gender $g$ and length $l ;$
$w_{a+1 / 2}^{g}$ is the mid-year weight of fish of gender $g$ and age $a$, at median length for that age;
$S_{f y l}^{g} \quad$ is the commercial selectivity of gender $g$ at length $l$ for year $y$, and fleet $f$;
$P_{a+1 / 2, l}^{g}$ is the mid-year proportion of fish of age $a$ and gender $g$ that fall in the length group $l$ (i.e.,

$$
\left.\sum_{l} P_{a+1 / 2, l}^{g}=1 \text { for all ages } a\right)
$$

The matrix $P$ is calculated under the assumption that length-at-age is log-normally distributed about a mean given by the von Bertalanffy equation, i.e.:
$l_{a} \sim N\left[\ln \left(l_{\infty}\left(1-e^{-\kappa\left(a-t_{0}\right)}\right)\right) ;\left(\frac{\theta_{a}}{l_{\infty}\left(1-e^{-\kappa\left(a-t_{0}\right)}\right)}\right)^{2}\right]$
(App.II.10)
where $\theta_{a}$ is the standard deviation of length-at-age $a$, which is estimated directly in the model fitting for age 0 , and for ages 1 and above a linear relationship applies, with species and gender-specific $\alpha$ and $\beta$ estimated in the model fitting procedure. A penalty is added so that $\theta_{a}$ is increasing with age.

## Exploitable and survey biomasses

The model estimate of the mid-year exploitable ("available") component of biomass for each species and fleet is calculated by converting the numbers-at-age into mid-year mass-at-age and applying natural and fishing mortality for half the year:
$B_{f y}^{e x}=\sum_{g} \sum_{a=0}^{m} w_{a+1 / 2}^{g} \tilde{S}_{f y a}^{g} N_{y a}^{g} e^{-M_{a}^{g} / 2}\left(1-\sum_{f} S_{f y a}^{g} F_{f y} / 2\right)$
(App.II.11)

The model estimate of the survey biomass at the start of the year (summer) is given by:
$B_{y}^{\text {surv }}=\sum_{g} \sum_{a=0}^{m_{s}} w_{a}^{g} \tilde{S}_{a}^{g, \text { sum }} N_{y a}^{g}$
(App.II.12)
and in mid-year (winter):
$B_{y}^{s u r v}=\sum_{g} \sum_{a=0}^{m} w_{a+1 / 2}^{g} \tilde{S}_{a}^{g, w i n} N_{y a}^{g} e^{-M_{a}^{g} / 2}\left(1-\sum_{f} S_{f y a}^{g} F_{f y} / 2\right)$
(App.II.13)
where
$\tilde{S}_{a}^{g, s u m / w i n}$ is the effective survey selectivity of gender $g$ for age $a$, converted from survey selectivity-at-length and selectivity-weighted weight-at-age in the same manner as for the commercial selectivity (eqns App.II. 8 and App.II.9), taking account of the being-year ( $\tilde{w}_{y, a}^{g, s u m}$ from $P_{a, l}^{g}$ ) or mid-year $\left(\tilde{w}_{y, a+1 / 2}^{g, \text { win }}\right.$ from $\left.P_{a+1 / 2, l}^{g}\right)$ nature of the surveys

Note that both the spring and autumn surveys are taken to correspond to winter (mid-year).
It is assumed that the resource is at the deterministic equilibrium that corresponds to an absence of harvesting at the start of the initial year considered, i.e., $B_{1}^{g, s p}=K^{g, s p}$, and year $y=1$ corresponds to 1917 when catches are taken to commence.

## MSY and related quantities

The equilibrium catch for a fully selected fishing proportion $F^{*}$ is calculated as:
$C\left(F^{*}\right)=\sum_{g} \sum_{a} w_{a+1 / 2}^{g} \tilde{S}_{a}^{g} F^{*} N_{a}^{g}\left(F^{*}\right) e^{-\left(\left(M_{a}^{g}+S_{a}^{g} F^{*}\right) / 2\right)}$
(App.II.14)
where
$S_{a}^{g}$ and $\tilde{S}_{a}^{g}$ are average selectivities and effective selectivities across all fleets, for the most recent five years;
$S_{a}^{g}=\frac{\sum_{y=2005}^{2009} \sum_{f} S_{f y a}^{g} F_{f y}}{\max \left(\sum_{y=2005}^{2009} \sum_{f} S_{f y a}^{g} F_{f y}\right)}$
$\tilde{S}_{a}^{g}=\frac{\sum_{y=2005}^{2009} \sum_{f} \tilde{S}_{f y a}^{g} F_{f y}}{\max \left(\sum_{y=2005}^{2009} \sum_{f} \tilde{S}_{f y a}^{g} F_{f y}\right)}$
where the maximum is taken over genders and ages; and with
$N_{a}^{g}\left(F^{*}\right)=\left\{\begin{array}{cc}R_{1}\left(F^{*}\right) & \text { for } a=1 \\ N_{a-1}^{g}\left(F^{*}\right) e^{-M_{a-1}^{g}\left(1-S_{a-1}^{g} F^{*}\right)} & \text { for } 1<a<m \\ \frac{N_{m-1}^{g}\left(F^{*}\right) e^{-M_{m-1}^{g}}\left(1-S_{m-1}^{g} F^{*}\right)}{\left(1-e^{-M_{m}^{g}}\left(1-S_{m}^{g} F^{*}\right)\right)} & \text { for } a=m\end{array}\right.$
where
$R_{1}\left(F^{*}\right)=\frac{\alpha B^{\rho, s p}\left(F^{*}\right)}{\beta+B^{\circ, s p}\left(F^{*}\right)}$
(App.II.18)
for a Beverton-Holt stock-recruitment relationship.

The maximum of $C\left(F^{*}\right)$ is then found by searching over $F^{*}$ to give $F_{\mathrm{MSY}}^{*}$, with the associated female spawning biomass given by
$B_{M S Y}^{\circ, s p}=\sum_{a} f_{a}^{\circ} w_{a}^{\circ} N_{a}^{\odot}\left(F_{\mathrm{MSY}}^{*}\right)$

## The likelihood function

The model is fit to CPUE and survey abundance indices, commercial and survey length frequencies, survey age-length keys, as well as to the stock-recruitment curve to estimate model parameters. Contributions by each of these to the negative of the $\log$-likelihood $(-\ell \mathrm{n} L)$ are as follows ${ }^{2}$.
CPUE relative abundance data
The likelihood is calculated by assuming that the observed abundance index (here CPUE) is lognormally distributed about its expected value:
$I_{y}^{i}=\hat{I}_{y}^{i} e^{\varepsilon_{y}^{i}} \quad$ or $\quad \varepsilon_{y}^{i}=\ln \left(I_{y}^{i}\right)-\ln \left(\hat{I}_{y}^{i}\right)$
where
$I_{y}^{i} \quad$ is the abundance index for year $y$ and series $i$ (which corresponds to a specified species and fleet)
$\hat{I}_{y}^{i}=\hat{q}^{i} \hat{B}_{f y}^{e x}$ is the corresponding model estimate, where $\widehat{B}_{f y}^{e x}$ is the model estimate of exploitable resource biomass, given by equation App.II.11,
$\hat{q}^{i} \quad$ is the constant of proportionality for abundance series $i$, and
$\varepsilon_{y}^{i} \quad$ from $N\left(0,\left(\sigma_{y}^{i}\right)^{2}\right)$.
In cases where the CPUE series are based upon species-aggregated catches (as available pre-1978), the corresponding model estimate is derived by assuming two types of fishing zones: z1) an "M. capensis only zone", corresponding to shallow water and z2) a "mixed zone" (Fig. App.II.1).

The total catch of hake of both species $(B S)$ by fleet $f$ in year $y\left(C_{B S, f y}\right)$ can be written as:
$C_{B S, f y}=C_{C, f y}^{z 1}+C_{C, f y}^{z 2}+C_{P, f y}$
(App.II.20)
where
$C_{C, f y}^{z 1} \quad$ is the M. capensis catch by fleet $f$ in year $y$ in the M. capensis only zone (z1),
$C_{C, f y}^{z 2} \quad$ is the M. capensis catch by fleet $f$ in year $y$ in the mixed zone (z2), and
$C_{P, f y} \quad$ is the M. paradoxus catch by fleet $f$ in year $y$ in the mixed zone.
Catch rate is assumed to be proportional to exploitable biomass. Furthermore, let $\gamma$ be the proportion of the M. capensis exploitable biomass in the mixed zone $\left(\gamma=B_{C, f y}^{e x, z 2} / B_{C, f y}^{e x}\right)$ (assumed to be constant throughout the period for simplicity) and $\psi_{f y}$ be the proportion of the effort of fleet $f$ in the mixed zone in year $y\left(\psi_{f y}=E_{f y}^{z 2} / E_{f y}\right)$, so that:

$$
\begin{align*}
& C_{C, f y}^{z 1}=q_{C}^{i, z 1} B_{C f y}^{e x, z 1} E_{f y}^{z 1}=q_{C}^{i, z 1}(1-\gamma) B_{C, f y}^{e x}\left(1-\psi_{f y}\right) E_{f y}  \tag{App.II.21}\\
& C_{C, f y}^{z 2}=q_{C}^{i, z 2} B_{C, f y}^{e x, z 2} E_{f y}^{z 2}=q_{C}^{i, z 2} \gamma B_{C, f y}^{e x} \psi_{f y} E_{f y} \text { and }  \tag{App.II.22}\\
& C_{P, f y}=q_{P}^{i} B_{P, f y}^{e x} E_{f y}^{z 2}=q_{P}^{i} B_{P, f y}^{e x} \psi_{f y} E_{f y} \tag{App.II.23}
\end{align*}
$$

where

[^2]$E_{f y}=E_{f y}^{z 1}+E_{f y}^{z 2}$ is the total effort of fleet $f$, corresponding to combined-species CPUE series $i$ which consists of the effort in the M. capensis only zone ( $E_{f y}^{z 1}$ ) and the effort in the mixed zone ( $E_{f y}^{z 2}$ ), and
$q_{C}^{i, z j} \quad$ is the catchability for $M$. capensis ( $C$ ) for abundance series $i$, and zone $z j$, and
$q_{P}^{i} \quad$ is the catchability for M. paradoxus $(P)$ for abundance series $i$.

It follows that:
$C_{C, f y}=B_{C, f y}^{e x} E_{f y}\left[q_{C}^{i, z 1}(1-\gamma)\left(1-\psi_{f y}\right)+q_{C}^{i, z 2} \gamma \psi_{f y}\right]$
(App.II.24)
$C_{P, f y}=B_{P, f y}^{e x} E_{f y} q_{P}^{i} \psi_{f y}$
(App.II.25)
From solving equations App.II. 24 and App.II. 25 :

$$
\begin{equation*}
s_{f y}=\frac{q_{C}^{i, z 1}(1-\gamma)}{\left\{\frac{C_{C, f y} B_{P, f y}^{e x} q_{P}^{i}}{B_{C, f y}^{e x} C_{P, f y}}-q_{C}^{i, z 2} \gamma+q_{C}^{i, z 1}(1-\gamma)\right\}} \tag{App.II.26}
\end{equation*}
$$

and:

$$
\begin{equation*}
\hat{I}_{y y}^{i}=\frac{C_{f y}}{E_{f y}}=\frac{C_{f y} B_{P, f y}^{e x} q_{P}^{i} \psi_{f y}}{C_{P, f y}} \tag{App.II.27}
\end{equation*}
$$

| Zone 1 (z1): | Zone 2 (z2): |
| :---: | :---: |
| M. capensis only | Mixed zone |
| M. capensis: | M. capensis: |
| biomass $\left(B_{C}^{z 1}\right)$, catch $\left(C_{C}^{z 1}\right)$ | biomass $\left(B_{C}^{z 2}\right)$, catch $\left(C_{C}^{z 2}\right)$ |

| Effort in zone $1\left(E^{z 1}\right)$ | biomass $\left(B_{P}\right)$, catch $\left(C_{P}\right)$ |

Fig. App.II.1: Diagrammatic representation of the two theoretical fishing zones.

Two species-aggregated CPUE indices are available: the ICSEAF west coast and the ICSEAF south coast series. For consistency, $q$ 's for each species (and zone) are forced to be in the same proportion:
$q_{s}^{S C}=r q_{s}^{W C}$
(App.II.28)
To correct for possible negative bias in estimates of variance $\left(\sigma_{y}^{i}\right)$ and to avoid according unrealistically high precision (and so giving inappropriately high weight) to the CPUE data, lower bounds on the standard deviations of the residuals for the logarithm of the CPUE series have been enforced; for the historic ICSEAF CPUE series (separate west coast and south coast series) the lower bound is set to 0.25 , and to 0.15 for the recent GLM-standardised CPUE series, i.e.: $\sigma^{\text {ICSEAF }} \geq 0.25$ and $\sigma^{G L M} \geq 0.15$.

The contribution of the CPUE data to the negative of the log-likelihood function (after removal of constants) is then given by:
$-\ln L^{\text {CPUE }}=\sum_{i} \sum_{y}\left\lfloor\ln \left(\sigma_{y}^{i}\right)+\left(\varepsilon_{y}^{i}\right)^{2} / 2\left(\sigma_{y}^{i}\right)^{2}\right]$
(App.II.29)
where
$\sigma_{y}^{i} \quad$ is the standard deviation of the residuals for the logarithms of index $i$ in year $y$.
Homoscedasticity of residuals for CPUE series is customarily assumed ${ }^{3}$, so that $\sigma_{y}^{i}=\sigma^{i}$ is estimated in the fitting procedure by its maximum likelihood value:

$$
\begin{equation*}
\hat{\sigma}^{i}=\sqrt{1 / n_{i} \sum_{y}\left(\ell \mathrm{n}\left(I_{y}^{i}\right)-\ell \mathrm{n}\left(\hat{I}_{y}^{i}\right)\right)^{2}} \tag{App.II.30}
\end{equation*}
$$

where $n_{i}$ is the number of data points for abundance index $i$.
In the case of the species-disaggregated CPUE series, the catchability coefficient $q^{i}$ for abundance index $i$ is estimated by its maximum likelihood value, which in the more general case of heteroscedastic residuals, is given by:
$\ln \hat{q}^{i}=\frac{\sum_{y}\left(\ln I_{y}^{i}-\ln \hat{B}_{f y}^{e x}\right) /\left(\sigma_{y}^{i}\right)^{2}}{\sum_{y} 1 /\left(\sigma_{y}^{i}\right)^{2}}$
(App.II.31)

In the case of the species-combined CPUE, $q_{C}^{W C, z 1}, q_{C}^{W C, z 2}, q_{P}^{W C}, r$ and $\gamma$ are directly estimated in the fitting procedure.

## Survey abundance data

Data from the research surveys are treated as relative abundance indices in a similar manner to the species-disaggregated CPUE series above, with survey selectivity function $S_{a}^{g, \text { sum/win }}$ replacing the commercial selectivity $S_{\text {fya }}^{g}$ (see equations App.II. 12 and App.II. 13 above, which also take account of the begin- or mid-year nature of the survey).

An estimate of sampling variance is available for most surveys and the associated $\sigma_{y}^{i}$ is generally taken to be given by the corresponding survey CV. However, these estimates likely fail to include all sources of variability, and unrealistically high precision (low variance and hence high weight) could hence be accorded to these indices. The contribution of the survey data to the negative log-likelihood is of the same form as that of the CPUE abundance data (see equation App.II.29). The procedure adopted takes into account an additional variance $\left(\sigma_{A}\right)^{2}$ which is treated as another estimable parameter in the minimisation process. This procedure is carried out enforcing the constraint that $\left(\sigma_{A}\right)^{2}>0$, i.e. the overall variance cannot be less than its externally input component.
In June 2003, the trawl gear on the Africana was changed and a different value for the multiplicative bias factor $q$ is taken to apply to the surveys conducted with the new gear. Calibration experiments have been conducted between the Africana with the old gear (hereafter referred to as the "old Africana") and the Nansen, and between the Africana with the new gear ("new Africana") and the Nansen, in order to provide a basis to relate the multiplicative biases of the Africana with the two types of gear ( $q_{\text {old }}$ and $q_{\text {new }}$ ). A GLM analysis assuming negative binomial distributions for the catches made (Brandão et al., 2004) provided the following estimates:

$$
\Delta \ell n q^{\text {capensis }}=-0.494 \quad \text { with } \sigma_{\Delta \ell n q} \text { capensis }=0.141 \quad \text { i.e. }\left(q^{\text {new }} / q^{\text {old }}\right)^{\text {capensis }}=0.610 \quad \text { and }
$$

[^3]$\Delta \ell n q^{\text {paradoxus }}=-0.053 \quad$ with $\sigma_{\Delta \ell n q}$ paradoxus $=0.117 \quad$ i.e. $\left(q^{\text {new }} / q^{\text {old }}\right)^{\text {paradoxus }}=0.948$
where
$\ell n q_{\text {new }}^{s}=\ell n q_{\text {old }}^{s}+\Delta \ell n q^{s} \quad$ with $s=$ capensis or paradoxus
(App.II.32)
No plausible explanation has yet been found for the particularly large extent to which catch efficiency for M. capensis is estimated to have decreased for the new research survey trawl net. It was therefore recommended (BENEFIT, 2004) that the ratio of the catchability of the new to the previous Africana net be below 1 , but not as low as the ratio estimated from the calibration experiments. $\Delta \ell n q^{\text {capensis }}$ is therefore taken as -0.223 , i.e. $\left(q^{\text {new }} / q^{\text {old }}\right)^{\text {capensis }}=0.8$.

The following contribution is therefore added as a penalty (or a prior in a Bayesian context) to the negative log-likelihood in the assessment:
$-\ell n L^{q-c h}=\left(\ell n q_{\text {new }}-\ell n q_{\text {old }}-\Delta \ell n q\right)^{2} / 2 \sigma_{\Delta \ell n q}^{2}$
A different length-specific selectivity is estimated for the "old Africana" and the "new Africana".
The survey's coefficients of catchability $q$ (for the survey with the old Africana gear) are constrained below 1 :
pen $^{q}=\sum_{i}\left(q_{\text {old }}^{i}-1\right)^{2} / 0.02^{2} \quad$ if $\quad q_{\text {old }}^{i}>1$
(App.II.34)

## Commercial proportions at length

Commercial proportions at length cannot be disaggregated by species and gender. The model is therefore fit to the proportions at length as determined for both species and gender combined.
The catches at length are computed as:
$C_{f y l}=\sum_{s} \sum_{g} \sum_{a=0}^{m} N_{s y a}^{g} F_{s f y} S_{s f y l}^{g} P_{s, a+1 / 2, l}^{g} e^{-M_{s a}^{g} / 2}\left(1-\sum_{f} S_{s f y a}^{g} F_{f y} / 2\right)$
(App.II.35)

With the predicted proportions at length:
$\hat{p}_{y l}^{i}=C_{f y l} / \sum_{l^{\prime}} C_{f y l^{\prime}}$
(App.II.36)

The contribution of the proportion at length data to the negative of the log-likelihood function when assuming an "adjusted" lognormal error distribution is given by:
$-\ell \mathrm{n} L^{\mathrm{length}}=0.1 \sum_{y} \sum_{l}\left\lfloor\ln \left(\sigma_{l e n}^{i} / \sqrt{p_{y l}^{i}}\right)+p_{y l}^{i}\left(\ln p_{y l}^{i}-\ln \hat{p}_{y l}^{i}\right)^{2} / 2\left(\sigma_{l e n}^{i}\right)^{2}\right\rfloor$
where
the superscript ' $i$ ' refers to a particular series of proportions at length data which reflect a specified fleet, and species (or combination thereof) and
$\sigma_{\text {len }}^{i} \quad$ is the standard deviation associated with the proportion at length data, which is estimated in the fitting procedure by:
$\hat{\sigma}_{\text {len }}^{i}=\sqrt{\sum_{y} \sum_{l} p_{y l}^{i}\left(\ln p_{y l}^{i}-\ln \hat{p}_{y l}^{i}\right)^{2} / \sum_{y} \sum_{l} 1}$
The initial 0.1 multiplicative factor is a somewhat arbitrary downweighting to allow for correlation between proportions in adjacent length groups. The coarse basis for this adjustment is the ratio of effective number of age-classes present to the number of length groups in the minimisation, under the argument that independence in variability is likely to be more closely related to the former.

Commercial proportions at length are incorporated in the likelihood function using equation App.II.37, for which the summation over length $l$ is taken from length $l_{\text {minus }}$ (considered as a minus group) to $l_{\text {plus }}$ (a plus group). The length for the minus- and plus-groups are fleet specific and are chosen so that typically a few percent, but no more, of the fish sampled fall into these two groups.

## Survey proportions at length

The survey proportions at length are incorporated into the negative of the log-likelihood in an analogous manner to the commercial catches-at-age, assuming an adjusted log-normal error distribution (equation App.II.36). In this case however, data are disaggregated by species, and for some surveys further disaggregated by gender.
$p_{s y l}^{g, \text { surv }}=\frac{C_{\text {syl }}^{g, \text { surv }}}{\sum^{g, \text { surv }}}$ is the observed proportion of fish of species $s$, gender $g$ and length $l$ from

$$
\sum_{l^{\prime}} C_{s y l^{\prime}}^{g, s u r v}
$$

survey surv in year $y$,
$\hat{p}_{s y l}^{g, \text { surv }}$ is the expected proportion of fish of species $s$, gender $g$ and length $l$ in year $y$ in the survey surv, given by:
$\hat{p}_{s y l}^{g, s u r v}=\frac{\sum_{a} S_{s l}^{g, s u m} P_{s a l}^{g} N_{s y a}^{g}}{\sum_{l^{\prime}} \sum_{a} S_{s l^{\prime}}^{g, s u m} P_{s a l}^{g} N_{s y a}^{g}}$
(App.II.39)
for begin-year (summer) surveys, or
$\hat{p}_{s y l}^{g, s u r v}=\frac{\sum_{a} S_{s l}^{g, w i n} P_{s, a+1 / 2, l}^{g} N_{s y a}^{g} e^{-M_{s a}^{g} / 2}\left(1-\sum_{f} S_{s f y a}^{g} F_{s f y} / 2\right)}{\sum_{l^{\prime}} \sum_{a} S_{s l^{\prime}}^{g, w i n} P_{s, a+1 / 2, l^{\prime}}^{g} N_{s y a}^{g} e^{-M_{s a}^{g} / 2}\left(1-\sum_{f} S_{s f y a}^{g} F_{s f y} / 2\right)}$
(App.II.40)
for mid-year (autumn, winter or spring) surveys.

## Age-length keys

Under the assumption that fish are sampled randomly with respect to age within each length-class, the contribution to the negative log-likelihood for the ALK data (ignoring constants) is:
$-\ln L^{A L K}=-w \sum_{i} \sum_{l} \sum_{a}\left[A_{i, l, a}^{o b s} \ln \left(\hat{A}_{i, l, a}\right)-A_{i, l, a}^{o b s} \ln \left(A_{i, l, a}^{o b s}\right)\right]$
where
$w \quad$ is a downweighting factor to allow for overdispersion in these data compared to the expectation for a multinomial distribution with independent data; for the moment this weight factor is set to 0.01 ,
$A_{i, a, l}^{\text {obs }}$ is the observed number of fish of age $a$ that fall in the length class $l$, for ALK $i$ (a specific combination of survey, year, species and gender),
$\hat{A}_{i, a, l} \quad$ is the model estimate of $A_{i, a, l}^{\text {obs }}$, computed as:
$\hat{A}_{i, a, l}=W_{i, l} \frac{C_{i, l} A_{a, l}}{\sum_{a^{\prime}} C_{i, l} A_{a, l}}$
where
$W_{i, l} \quad$ is the number of fish in length class $l$ that were aged for ALK $i$,
$A_{a^{\prime}, l}=\sum_{a} P\left(a^{\prime} \mid a\right) A_{a, l}$ is the ALK for age $a$ and length $l$ after accounting for age-reading error,
with $P\left(a^{\prime} \mid a\right)$, the age-reading error matrix, representing the probability of an animal of true age $a$ being aged to be that age or some other age $a$.

Age-reading error matrices have been computed for each reader and for each species in Rademeyer (2009).

When multiple readers age the same fish, these data are considered to be independent information in the model fitting.

## Stock-recruitment function residuals

The stock-recruitment residuals are assumed to be log-normally distributed. Thus, the contribution of the recruitment residuals to the negative of the log-likelihood function is given by:
$-\ell n L^{S R}=\sum_{s}\left[\sum_{y=y 1}^{y 2} \varsigma_{s y}{ }^{2} / 2 \sigma_{R}^{2}+\left(\sum_{y=y 1}^{y 2} \varsigma_{s y}\right)^{2} / 0.01^{2}\right]$
where
$\zeta_{s y} \quad$ is the recruitment residual for species $s$, and year $y$, which is assumed to be log-normally distributed with standard deviation $\sigma_{R}$ and which is estimated for year $y l$ to $y 2$ (see equation App.II.4) (estimating the stock-recruitment residuals is made possible by the availability of catch-at-age data, which give some indication of the age-structure of the population); and
$\sigma_{R} \quad$ is the standard deviation of the log-residuals, which is input.
The stock-recruitment residuals are estimated for years 1985 to 2006, with recruitment for other years being set deterministically (i.e. exactly as given by the estimated stock-recruitment curve) as there is insufficient catch-at-age information to allow reliable residual estimation for earlier years. A limit on the recent recruitment fluctuations is set by having the $\sigma_{R}$ (which measures the extent of variability in recruitment - see equation - App.II.43) decreasing linearly from 0.45 in 2004 to 0.1 in 2009, effectively forcing recruitment over the last years to lie closer to the stock-recruitment relationship curve.

The second term on the right hand side is introduced to force the average of the residuals estimated over the period from $y 1$ to $y 2$ to be close to zero, for reasons elaborated in the main text.

## Model parameters

## Estimable parameters

The primary parameters estimated are the species-specific female virgin spawning biomass $\left(K_{s}^{q_{s p}}\right)$ and "steepness" of the stock-recruitment relationship $\left(h_{s}\right)$. The standard deviations $\sigma^{i}$ for the CPUE series residuals (the species-combined as well as the GLM-standardised series) as well as the additional variance $\left(\sigma_{A}^{i}\right)^{2}$ for each survey abundance series are treated as estimable parameters in the minimisation process. Similarly, in the case of the species-combined CPUE, $q_{C}^{W C, z 1}, q_{C}^{W C, z 2}, q_{P}^{W C}, r$ and $\gamma$ are directly estimated in the fitting procedure.
The species- and gender-specific von Bertalanffy growth curve parameters ( $L_{5}, \kappa$ and $t_{0}$ ) are estimated directly in the model fitting process, as well as $\theta_{0}, \theta_{1}$ and $\theta_{14}$, values used to compute the standard deviation of the length-at-age $a$.

The following parameters are also estimated in the model fits undertaken (if not specifically indicated as fixed).

## Natural mortality:

Natural mortality $\left(M_{s a}^{g}\right)$ is assumed to be age-specific and is calculated using the following functional form:

$$
M_{s a}^{\circ}=\left\{\begin{array}{lll}
M_{s 2}^{\circ} & \text { for } & a \leq 1  \tag{App.II.44}\\
\alpha_{s}^{M}+\frac{\beta_{s}^{M}}{a+1} & \text { for } & 2 \leq a \leq 5 \\
M_{s 5}^{\circ} & \text { for } & a>5
\end{array}\right.
$$

and

$$
\begin{equation*}
M_{s a}^{\text {males }}=v^{s} M_{s a}^{\text {females }} \tag{App.II.45}
\end{equation*}
$$

$M_{s 0}$ and $M_{s 1}$ are set equal to $M_{s 2}\left(=\alpha_{s}^{M}+\beta_{s}^{M} / 3\right)$ as there are no data (hake of ages younger than 2 are rare in catch and survey data) which would allow independent estimation of $M_{s 0}$ and $M_{s 1}$.

When $M$ values are estimated in the fit, a penalty is added to the total $-\operatorname{lnL}$ so that $M_{s 2} \geq M_{s 5}$ :

$$
p e n^{M}=\sum_{s}\left(M_{s 5}-M_{s 2}\right)^{2} / 0.01^{2} \quad \text { if } M_{s 2}<M_{s 5}
$$

(App.II.46)

## Stock-recruitment residuals:

Stock-recruitment residuals $\varsigma_{s y}$ are estimable parameters in the model fitting process. They are estimated separately for each species from 1985 to the present, and set to zero pre-1985 because there are no catch-at-length data for that period to provide the information necessary to inform estimation.

Table App.II. 1 summarises the estimable parameters, excluding the selectivity parameters.

## Survey fishing selectivity-at-length:

The survey selectivities are estimated directly for seven pre-determined lengths for M. paradoxus and M. capensis. When the model was fitted to proportion-at-age rather than proportion-at-length, survey selectivities were estimated directly for each age (i.e. seven age classes). The lengths at which selectivity is estimated directly are survey specific (linear between the minus and plus groups) and are given in Table App.II.2. Between these lengths, selectivity is assumed to change linearly. The slope from lengths $l_{\text {minus }}$ to $l_{\text {minus }}+1$ is assumed to continue exponentially to lower lengths to length $l$, and similarly the slope from lengths $l_{\text {plus }}-1$ to $l_{\text {plus }}$ for $M$. paradoxus and $M$. capensis to continue for greater lengths.
For the south coast spring and autumn surveys, gender-specific selectivities are estimated for $M$. paradoxus. Furthermore, the female selectivities are scaled down by a parameter estimated for each of these two surveys to allow for the male predominance in the survey catch.
A penalty is added to the total $-\ln L$ to smooth the selectivities:

$$
\begin{equation*}
\text { pen }^{s u r v s}=\sum_{i} \sum_{L=L_{1}+1}^{L_{7}-1} 3\left(S_{L-1}^{i}-2 S_{L}^{i}+S_{L+1}^{i}\right)^{2} \tag{App.II.47}
\end{equation*}
$$

where $i$ is a combination of survey, species and gender.

## Commercial fishing selectivity-at-length:

The fishing selectivity-at-length (gender independent) for each species and fleet, $S_{s f l}$, is estimated in terms of a logistic curve given by:

$$
\begin{equation*}
S_{s f l}=\left[1+\exp \left(-\left(l-l_{s f}^{c}\right) / \delta_{s f}^{c}\right)\right]^{-1} \tag{App.II.45}
\end{equation*}
$$

where
$l_{s f}^{c} \mathrm{~cm}$ is the length-at-50\% selectivity,
$\delta_{s f}^{c} \mathrm{~cm}^{-1}$ defines the steepness of the ascending limb of the selectivity curve.
The selectivity is sometimes modified to include a decrease in selectivity at larger lengths, as follows:
$S_{s f l}=S_{s, f, l-1} e^{-s_{s f l}} \quad$ for $l>l_{\text {slope }}$,
(App.II.46)
where
$s_{\text {sfl }}$ measures the rate of decrease in selectivity with length for fish longer than $l_{\text {slope }}$ for the fleet concerned, and is referred to as the "selectivity slope".
$l_{\text {slope }}$ is fixed externally from the model, values for each fleet and species are given in
Periods of fixed and changing selectivity have been assumed for the offshore trawl fleet to take account of the change in the selectivity at low ages over time in the commercial catches, likely due to the phasing out of the (illegal) use of net liners to enhance catch rates.
On the south coast, for M. paradoxus, the female offshore trawl selectivity (only the trawl fleet is assumed to catch M. paradoxus on the south coast) is scaled down by a factor taken as the average of those estimated for the south coast spring and autumn surveys. Although there is no gender information for the commercial catches, the south coast spring and autumn surveys catch a much higher proportion of male M. paradoxus than female (ratios of about $7: 1$ and $3.5: 1$ for spring and autumn respectively). This is assumed to reflect a difference in distribution of the two genders which would therefore affect the commercial fleet similarly.
Details of the fishing selectivities (including the number of parameters estimated) used in the assessment are shown in Table App.II.4.

## Input parameters and other choice for application to hake

Age-at-maturity:
The proportion of fish of species $s$, gender $g$ and length $l$ that are mature is assumed to follow a logistic curve with the parameter values given below (from Fairweather and Leslie, 2008, "stage 2, >40cm" for females and Fairweather, pers. commn for males):

|  | $l_{50}(\mathrm{~cm})$ | N |
| ---: | :---: | :---: |
| M. paradoxus: |  |  |
| Males | 28.63 | 5.07 |
| Females | 42.24 | 4.46 |
| M. capensis: |  |  |
| Males | 34.35 | 7.38 |
| Females | 40.80 | 7.51 |

Maturity-at-length is then converted to maturity-at-age as follows:

$$
\begin{equation*}
f_{s a}^{g}=\sum_{l} f_{s l}^{g} P_{a, l}^{g} \tag{App.II.47}
\end{equation*}
$$

## Weight-at-length:

The weight-at-length for each species and gender is calculated from the mass-at-length function, with values of the parameters for this function listed below (from Fairweather, 2008, taking the average of the west and south coasts):

|  | $\perp\left(\mathrm{gm} / \mathrm{cm}^{\perp}\right)$ | $\perp$ |
| ---: | :---: | :---: |
| M. paradoxus: |  |  |
| Males | 0.007541 | 2.988 |
| Females | 0.005836 | 3.065 |
| M. capensis: |  |  |
| Males | 0.006307 | 3.061 |
| Females | 0.005786 | 3.085 |

## Minus- and plus-groups

Because of a combination of gear selectivity and mortality, a relatively small number of fish in the smallest and largest length classes are caught. In consequence, there can be relatively larger errors (in terms of variance) associated with these data. To reduce this effect, the assessment is conducted with minus- and plus-groups obtained by summing the data over the lengths below and above $l_{\text {minus }}$ and $l_{\text {plus }}$ respectively. The minus- and plus-group used are given in Table App.II. 5 (and plotted in Figs.I. 2 and 3). Furthermore, the proportions at length data (both commercial and survey) are summed into 2 cm length classes for the model fitting.

Table App.II.1: Parameters estimated in the model fitting procedure, excluding selectivity parameters.

|  | No of parameters | Parameters estimated |

## ADDENDUM TO:

## Proposed Reference Set for the South African hake resource to be used in OMP-2010 testing

Rebecca A Rademeyer and Doug S Butterworth

February 2010

Further robustness/sensitivity tests have been conducted; they are detailed in Table Add1. Table Add2 summarises the key management quantities for these robustness/sensitivity tests, while Table Add3 compares their different contributions to the total negative log-likelihood.

Fig. Add1 plots the estimated spawning biomass trajectories for these further tests. The fit of Rob14 (giving more weight to the recent CPUE and survey abundance series) to the CPUE and survey series are shown in Figs Add2 and Add3 and compared to the RC (= RS1) fit. The time-series of standardised recruitment residuals for Rob15 (no shrinkage of recent recruitment towards the stock-recruitment relationship prediction) are compared to those of the RC in Fig. Add4.

## Comments

Rob12 (changed selectivity slopes
The likelihood deteriorates, often substantially, but there is not much change to estimates of key management-related quantities (Tables Add2 and Add3).

## Rob13 (decrease in $K$ )

Productivity (MSY) estimates are lower, and M. capensis is estimated to be depleted to a greater extent (Table Add2).

Rob14 (more weight to fitting recent abundance index data)
The only notable difference to the fit is that the model better reflects recent higher CPUE values for $M$. paradoxus on the south coast. M. paradoxus is estimated to be depleted to a lesser, but M. capensis to a greater extent (Figs Add2 and Add3).

## Rob15 (no shrinkage on recent recruitments)

Immediate recruitment to the fishery is estimated to be better for $M$. capensis, but worse for $M$. paradoxus, compared to the RC (Fig. Add4).

## Rob16 (reduced M at larger ages for RS2)

This reduces the pre-exploitation biomass $K$, which might be considered unrealistically high for this scenario, without making much difference to estimates of key management-related quantities (Table Add2).

Table Add1: Description of the further robustness/sensitivity tests.

|  | Shift center |  | M | Other |
| :---: | :---: | :---: | :---: | :---: |
| Rob12 |  | as RC |  | All commercial and survey selectivity slopes (in $\mathrm{cm}^{-1}$ ): a) +0.04 , b) +0.02 , c) -0.04 and d) -0.02 |
| Rob13 |  | as RC |  | Change in $K$ ( $30 \%$ linear decrease btw 1980 and 2000 for both spp) |
| Rob14 |  | as RC |  | Added weighting to recent data to fit recent abundance indices more closely ( 5 times more weight on last 5 year's CPUE and survey abundance indices) |
| Rob15 |  | as RC |  | No shrinkage of recent recruitments towards the stock-recruitment relationship prediction |
| Rob 16 |  | as RS2 |  | Increasing $M$ at large ages (linear from 0.25 at age 8 to 1 at age 15) |

Table Add2: Estimates of management quantities for the RC (= RS1) and the further robustness/sensitivity tests. Values in bold have been fixed. Results for RS2 are included for comparison with Rob16. For Rob13, $K^{s p}$ and quantities relative to it are in terms of the 1917 estimate

|  | -lnL | $K^{s p}$ | $h$ | $\begin{gathered} B^{s p}{ }_{2009} \\ / K^{s p} \end{gathered}$ | $\begin{gathered} \text { M. par } \\ B_{M S Y}^{s p} \\ / K^{s p} \end{gathered}$ | radoxus $\begin{gathered} B^{s p}{ }_{2009} / \\ B^{s p}{ }_{M S Y} \end{gathered}$ | MSY | $M_{2}$ | $M_{5+}$ | $K^{s p}$ | $h$ | $\begin{gathered} B^{s p}{ }_{2009} \\ / K^{s p} \end{gathered}$ | $\begin{gathered} \quad \text { M. cap } \\ B^{s p}{ }_{M S Y} B \\ / K^{s p} \end{gathered}$ | apensis $\begin{gathered} B^{s p}{ }_{2009} / \\ B^{s p}{ }_{M S Y} \end{gathered}$ | MSY | $M_{2}$. | $M_{5+}$ | 2009 species ratio $B^{s p}$ |
